Magnetic Resonance Imaging Improves 3-Month Outcome Prediction in Mild Traumatic Brain Injury

Esther L. Yuh, MD, PhD,[1,2] Pratik Mukherjee, MD, PhD,[1,2] Hester F. Lingsma, PhD,[3] John K. Yue, BS,[1,4] Adam R. Ferguson, PhD,[1,4] Wayne A. Gordon, PhD,[5] Alex B. Valadka, MD,[6] David M. Schnyer, PhD,[7] David O. Okonkwo, MD, PhD,[8] Andrew I. R. Maas, MD, PhD,[9] Geoffrey T. Manley, MD, PhD,[1,4] and the TRACK-TBI Investigators

Objective: To determine the clinical relevance, if any, of traumatic intracranial findings on early head computed tomography (CT) and brain magnetic resonance imaging (MRI) to 3-month outcome in mild traumatic brain injury (MTBI).
Methods: One hundred thirty-five MTBI patients evaluated for acute head injury in emergency departments of 3 LEVEL I trauma centers were enrolled prospectively. In addition to admission head CT, early brain MRI was performed 12 ± 3.9 days after injury. Univariate and multivariate logistic regression were used to assess for demographic, clinical, socioeconomic, CT, and MRI features that were predictive of Extended Glasgow Outcome Scale (GOS-E) at 3 months postinjury.
Results: Twenty-seven percent of MTBI patients with normal admission head CT had abnormal early brain MRI. CT evidence of subarachnoid hemorrhage was associated with a multivariate odds ratio of 3.5 ($p = 0.01$) for poorer 3-month outcome, after adjusting for demographic, clinical, and socioeconomic factors. One or more brain contusions on MRI, and ≥4 foci of hemorrhagic axonal injury on MRI, were each independently associated with poorer 3-month outcome, with multivariate odds ratios of 4.5 ($p = 0.01$) and 3.2 ($p = 0.03$), respectively, after adjusting for head CT findings and demographic, clinical, and socioeconomic factors.
Interpretation: In this prospective multicenter observational study, the clinical relevance of abnormal findings on early brain imaging after MTBI is demonstrated. The addition of early CT and MRI markers to a prognostic model based on previously known demographic, clinical, and socioeconomic predictors resulted in a >2-fold increase in the explained variance in 3-month GOS-E.

ANN NEUROL 2013;73:224–235

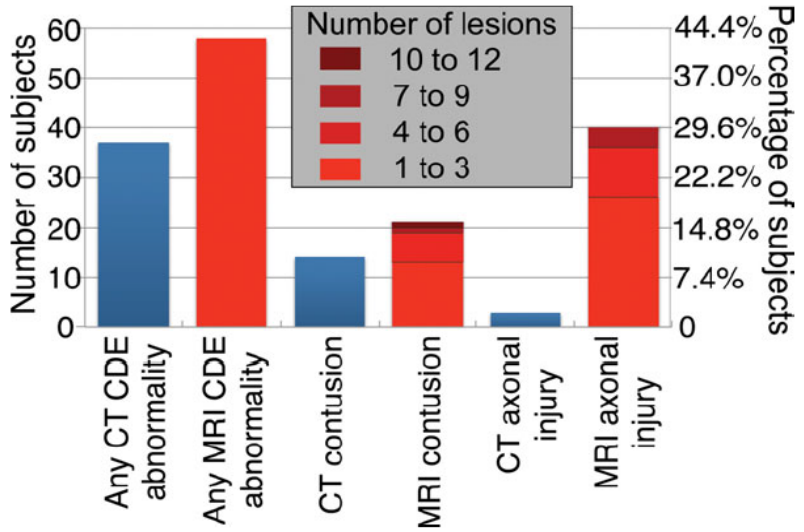

FIGURE 1: Incidence of computed tomography (CT) versus magnetic resonance imaging (MRI) traumatic brain injury common data element (CDE) abnormalities in 135 study participants. For MRI evidence of contusion and MRI evidence of hemorrhagic axonal injury, progressively darker shades of red indicate larger numbers of lesions (*gray legend*). Study participants with CT evidence of brain contusion had, in most cases, evidence of 1 or 2 hemorrhagic contusions, with no CT demonstrating >3 convincing brain contusions. CT showed evidence of hemorrhagic axonal injury in 3 of 135 study participants, all with 1 to 3 foci of injury. Cooper,[2] Kristen Dams-O'Connor,[7] Wayne A. Gordon,[7] Allison J. Hricik,[1] Kerri Lawless,[1] David Menon,[8] David M. Schnyer,[9] and Mary J. Vassar[2]

Abstract

Glial fibrillary acidic protein and its breakdown products (GFAP-BDP) are brain-specific proteins released into serum as part of the pathophysiological response after traumatic brain injury (TBI). We performed a multi-center trial to validate and characterize the use of GFAP-BDP levels in the diagnosis of intracranial injury in a broad population of patients with a positive clinical screen for head injury. This multi-center, prospective, cohort study included patients 16–93 years of age presenting to three level 1 trauma centers with suspected TBI (loss of consciousness, post-trauma amnesia, and so on). Serum GFAP-BDP levels were drawn within 24 h and analyzed, in a blinded fashion, using sandwich enzyme-linked immunosorbent assay. The ability of GFAP-BDP to predict intracranial injury on admission computed tomography (CT) as well as delayed magnetic resonance imaging was analyzed by multiple regression and assessed by the area under the receiver operating characteristic curve (AUC). Utility of GFAP-BDP to predict injury and reduce unnecessary CT scans was assessed utilizing decision curve analysis. A total of 215 patients were included, of which 83% suffered mild TBI, 4% moderate, and 12% severe; mean age was 42.1 ± 18 years. Evidence of intracranial injury was present in 51% of the sample (median Rotterdam Score, 2; interquartile range, 2). GFAP-BDP demonstrated very good predictive ability (AUC = 0.87) and demonstrated significant discrimination of injury severity (odds ratio, 1.45; 95% confidence interval, 1.29–1.64). Use of GFAP-BDP yielded a net benefit above clinical screening alone and a net reduction in unnecessary scans by 12–30%. Used in conjunction with other clinical information, rapid measurement of GFAP-BDP is useful in establishing or excluding the diagnosis of radiographically apparent intracranial injury throughout the spectrum of TBI. As an adjunct to current screening practices, GFAP-BDP may help avoid unnecessary CT scans without sacrificing sensitivity (Registry: ClinicalTrials.gov Identifier: NCT01565551).

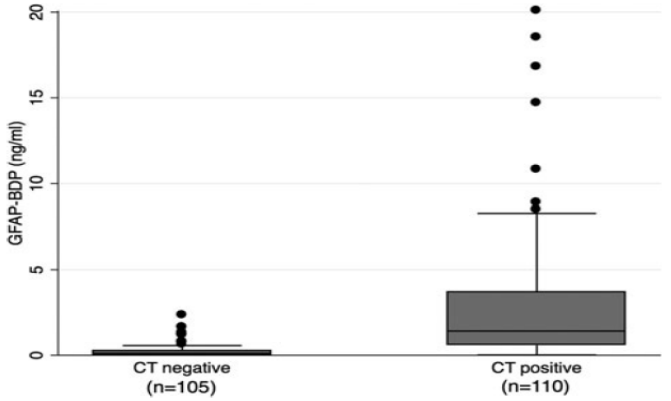

FIG. 1. Box plots showing median levels of GFAP-BDP measured on admission in two groups of patients. Boxes show interquartile ranges, and I bars represent highest and lowest values. CT, computed tomography;GFAP-BDP, glial fibrillary acidic protein and its breakdown products.

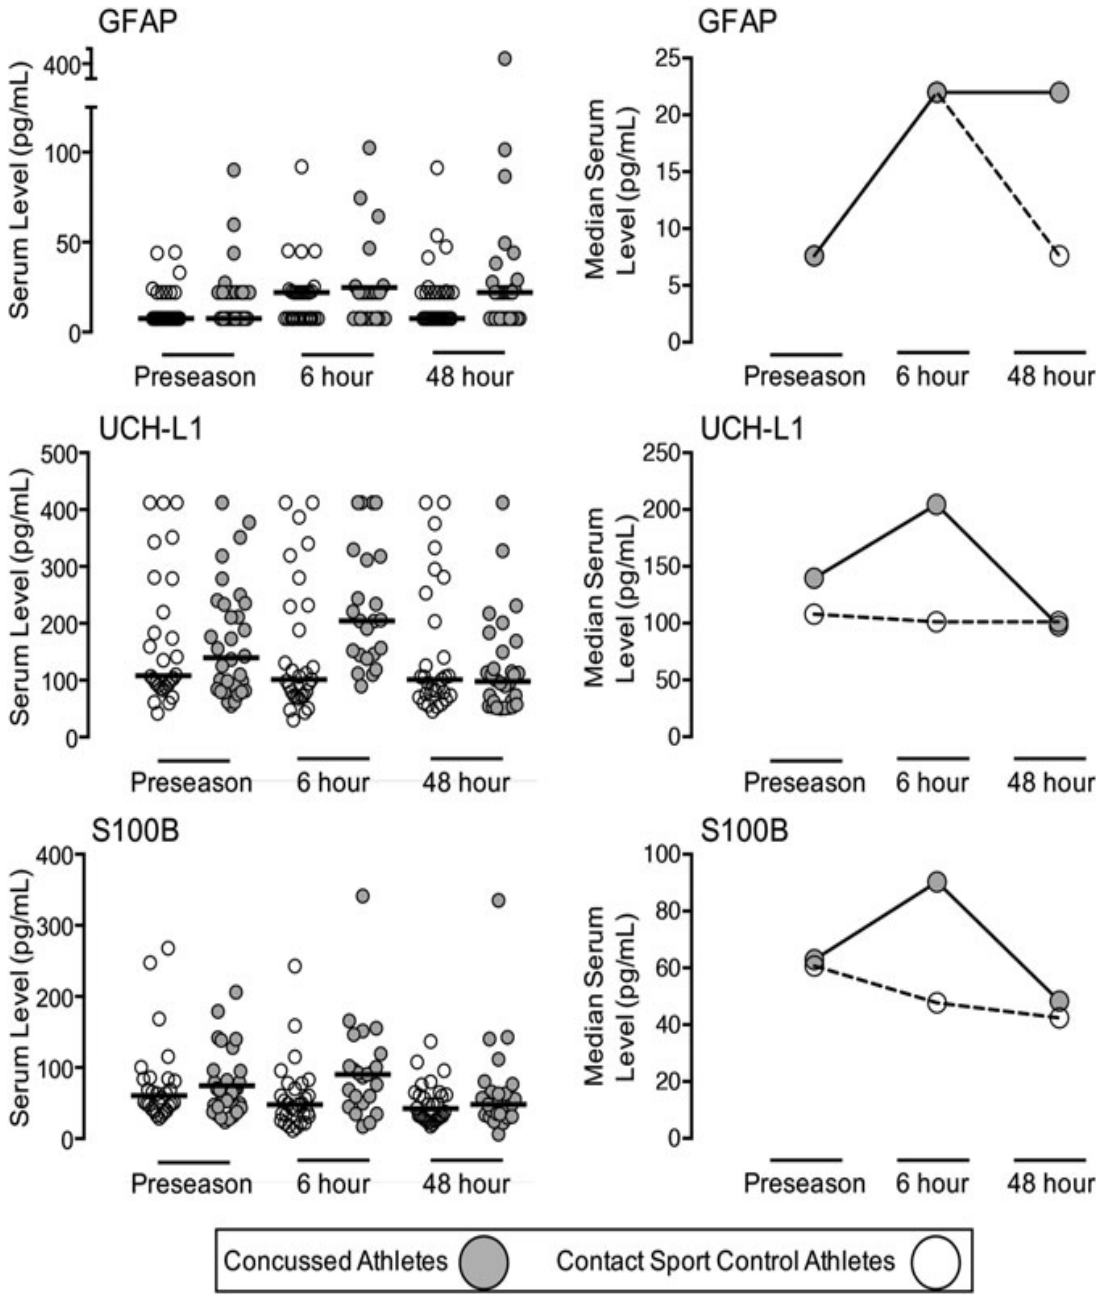
Prospective Assessment of Acute Blood Markers of Brain Injury in Sport-Related Concussion

Timothy B. Meier,[1,2] Lindsay D. Nelson,[1,3] Daniel L. Huber,[1] Jeffrey J. Bazarian,[4] Ronald L. Hayes,[5] and Michael A. McCrea[1,3]

Abstract

There is a pressing need to identify objective biomarkers for the assessment of sport-related concussion (SRC) to reduce the reliance on clinical judgment for the management of these injuries. The goal of the current study was to prospectively establish the acute effects of SRC on serum levels of S100 calcium-binding protein beta (S100B), glial fibrillary acidic protein (GFAP), and ubiquitin C-terminal hydrolase-L1 (UCH-L1). Collegiate and high school football players were enrolled and provided blood at pre-season. Injured athletes participated in follow-up visits at ~6 and 24–48 h following documented SRC ($n=32$). Uninjured football players participated in similar follow-up visits and served as controls ($n=29$). The median time between injury and blood collection was 2 h (6 h visit) and 22.5 h (24–48 h visit) in concussed athletes. Concussed athletes had significantly elevated UCH-L1 levels at the 6 h visit relative to pre-season levels ($Z=2.22$, $p=0.03$) and levels in control athletes ($Z=3.02$, $p=0.003$). Concussed athletes also had elevated S100B at 6 h relative to pre-season ($Z=2.07$, $p=0.04$) and controls ($Z=2.75$, $p=0.006$). Both markers showed fair discrimination between concussed and control athletes (UCH-L1 area under receiver operating characteristic curve [AUC] [95% CI] = 0.74 [0.61–0.88], S100B AUC = 0.72 [0.58–0.87]). Percent-change of UCH-L1 and S100B at 6 h relative to pre-season also showed fair discrimination (AUC = 0.79 [0.66–0.92] and AUC = 0.77 [0.64–0.90]). GFAP levels did not differ between groups or in concussed athletes relative to pre-season. This study provides prospective evidence of significant increases in serum levels of UCH-L1 and S100B during the early acute period following SRC, and lays the foundation for future studies examining the clinical potential for blood-based biomarkers in the early detection of concussion.



ARTICLE CLASS OF EVIDENCE

Acute elevation of serum inflammatory markers predicts symptom recovery after concussion

Morgan E. Nitta, MS, Jonathan Savitz, PhD, Lindsay D. Nelson, PhD, T. Kent Teague, PhD, James B. Hoelzle, PhD, Michael A. McCrea, PhD, and Timothy B. Meier, PhD

tmeier@mcw.edu

Neurology® 2019;93:e497-e507. doi:10.1212/WNL.0000000000007864

Objective

To test the hypothesis that acute elevations in serum inflammatory markers predict symptom recovery after sport-related concussion (SRC).

Methods

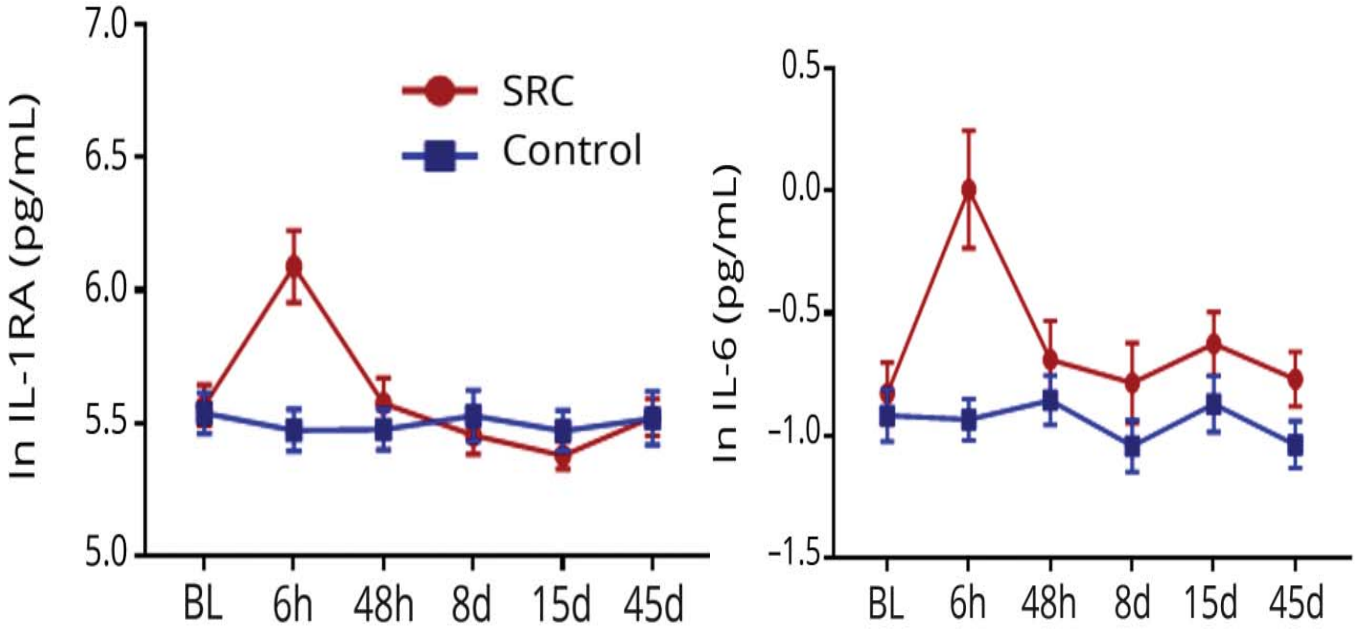
High school and collegiate football players (n = 857) were prospectively enrolled. Forty-one athletes with concussion and 43 matched control athletes met inclusion criteria. Serum levels of interleukin (IL)–6, IL-1β, IL-10, tumor necrosis factor, C-reactive protein, interferon-γ, and IL-1 receptor antagonist and Sport Concussion Assessment Tool, 3rd edition (SCAT3) symptom severity scores were collected at a preinjury baseline, 6 and 24–48 hours postinjury, and approximately 8, 15, and 45 days following concussion. The number of days that athletes were symptomatic following SRC (i.e., duration of symptoms) was the primary outcome variable.

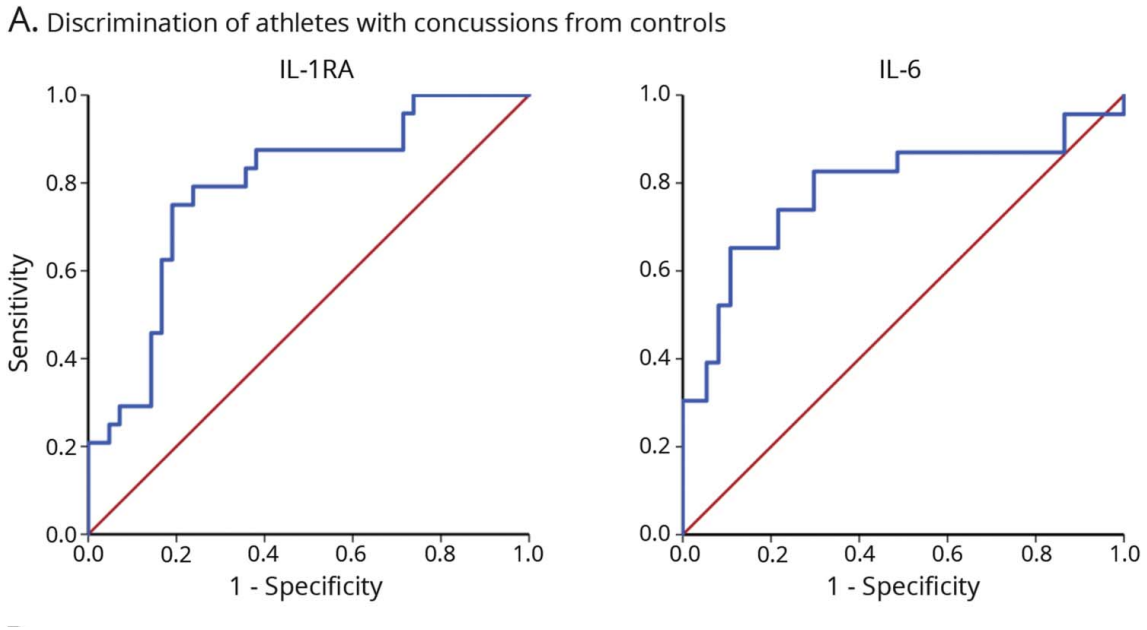
Results

IL-6 and IL-1RA were significantly elevated in athletes with concussion at 6 hours relative to preinjury and other postinjury visits, as well as compared to controls (*ps* ≤ 0.001). IL-6 and IL-1RA significantly discriminated concussed from control athletes at 6 hours postconcussion (IL-6 area under receiver operating characteristic curve 0.79 [95% confidence interval (CI) 0.65–0.92], IL-1RA AUC 0.79 [95% CI 0.67–0.90]). Further, IL-6 levels at 6 hours post-concussion were significantly associated with the duration of symptoms (hazard ratio for symptom recovery = 0.61 [95% CI 0.38–0.96], $p = 0.031$).

Conclusions

Results support the potential utility of IL-6 and IL-1RA as serum biomarkers of SRC and demonstrate the potential of these markers in identifying athletes at risk for prolonged recovery after SRC.





TBI Outcome Measurement

Glasgow Outcome Scale – Extended (GOSE)

1	**Dead**	
2	**Vegetative State (VS)**	Condition of unawareness with only reflex responses but with periods of spontaneous eye opening
3	**Severe Disability – Lower (SD–)**	Dependence on daily support for mental or physical disability or both. If the patient can be left alone for more than 8 hours at home, it is upper level of SD; if not, then it is low level of SD
4	**Severe Disability – Upper (SD+)**	
5	**Moderate Disability – Lower (MD–)**	Patients have some disability such as aphasia, hemiparesis or epilepsy and/or deficits of memory or personality but are able to look after themselves. They are independent at home but dependent outside. If they are able to return to work event with special arrangement it is upper level of MD; if not then it is low level of MD.
6	**Moderate Disability – Upper (MD+)**	
7	**Good Recovery – Lower (GR–)**	Resumption of normal life with the capacity to work even if pre-injury status has not been achieved. Some patients have minor neurological or psychological deficits. If these deficits are not disabling then it is upper level of GR; if disabling, then it is lower level of GR.
8	**Good Recovery – Upper (GR+)**

Validating Multi-Dimensional Outcome Assessment Using the Traumatic Brain Injury Common Data Elements: An Analysis of the TRACK-TBI Pilot Study Sample

Lindsay D. Nelson,[1] Jana Ranson,[2] Adam R. Ferguson,[3] Joseph Giacino,[4] David O. Okonkwo,[5] Alex B. Valadka,[6] Geoffrey T. Manley,[7] Michael A. McCrea,[1] and the TRACK-TBI Investigators

Abstract

The Glasgow Outcome Scale-Extended (GOSE) is often the primary outcome measure in clinical trials for traumatic brain injury (TBI). Although the GOSE's capture of global functional outcome has several strengths, concerns have been raised about its limited ability to identify mild disability and failure to capture the full scope of problems patients exhibit after TBI. This analysis examined the convergence of disability ratings across a multi-dimensional set of outcome domains in the Transforming Research and Clinical Knowledge in Traumatic Brain Injury (TRACK-TBI) Pilot Study. The study collected measures recommended by the TBI Common Data Elements (CDE) Workgroup. Patients presenting to three emergency departments with a TBI of any severity enrolled in TRACK-TBI prospectively after injury; outcome measures were collected at 3 and 6 months post-injury. Analyses examined frequency of impairment and overlap between impairment status across the CDE outcome domains of Global Level of Functioning (GOSE), Neuropsychological (cognitive) Impairment, Psychological Status, TBI Symptoms, and Quality of Life. GOSE score correlated in the expected direction with other outcomes (mean [*M*] Spearman's rho = 0.21 and 0.49 with neurocognitive and self-report outcomes, respectively). The subsample in the Upper Good Recovery (GOSE 8) category appeared quite healthy across most other outcomes, although 19.0% had impaired executive functioning (Trail Making Test Part B). A significant minority of participants in the Lower Good Recovery subgroup (GOSE 7) met criteria for impairment across numerous other outcome measures. The findings highlight the multi-dimensional nature of TBI recovery and the limitations of applying only a single outcome measure.

Disability Caused by Minor Head Injury

Rebecca W. Rimel, R.N., N.P., Bruno Giordani, M.A., Jeffrey T. Barth, Ph.D., Thomas J. Boll, Ph.D., and John A. Jane, M.D., Ph.D.

Departments of Neurosurgery (R.W.R., J.A.J.), Neurology (B.G.), and Psychiatry (J.T.B.), University of Virginia Medical Center, Charlottesville, Virginia, and Department of Psychiatry (T.J.B.), University of Health Sciences—The Chicago Medical School, Chicago, Illinois

The authors studied 538 patients who had sustained minor head trauma, which was defined as a history of unconsciousness of 20 minutes or less, a Glasgow Coma Scale score of 13 to 15, and hospitalization not exceeding 48 hours. Of these patients, 424 were evaluated 3 months after injury. The follow-up evaluation included a history of events since the accident, assessment of subjective complaints and objective measures such as employment status, a neurological examination, a psychosocial assessment designed for estimating life stress, and a neuropsychological test battery to measure higher cortical function. Of these 424 patients, 79% complained of persistent headaches, and 59% described problems with memory. Of the patients who had been gainfully employed before the accident, 34% were unemployed 3 months later. Comparisons were then made between the employed and the unemployed groups. Three explanations for the high rate of unemployment were examined. (*a*) *Evidence of organic brain damage:* Although the neurological examination was completely normal in nearly all patients, neuropsychological testing demonstrated some problems with attention, concentration, memory, or judgment in most of the 69 patients evaluated. (*b*) *Psychological responses to the injury:* Emotional stress caused by persistent symptoms seems to be a significant factor in the long term disability of these patients. (*c*) *Litigation and compensation:* These factors have a minimal role in determining outcome after minor head injury. In conclusion, the most striking observations of these studies are the high rates of morbidity and unemployment in patients 3 months after a seemingly insignificant head injury and the evidence that many of these patients may have, in fact, suffered organic brain damage. Key Points

Question Do patients with mild traumatic brain injury (mTBI) receive adequate levels of follow-up care?

Findings In a cohort study using data on 831 patients with mTBI presenting to the emergency department at 1 of 11 level I trauma centers across the United States, 42% of patients reported receiving educational material at discharge and 44% reported seeing a physician or other medical practitioner within 3 months after injury. Among patients with 3 or more moderate to severe postconcussive symptoms, only 52% reported having seen a practitioner within 3 months following the injury.

Meaning A large proportion of patients with mTBI do not receive follow-up care after injury even when they experience ongoing postconcussive symptoms.

It's Tough to Get Precision Care with No Care
